On superconducting mechanism in the iron-based layered superconductors

L. S. Mazov
Institute for Physics of Microstructures, Russian Academy of Sciences, Nizhny Novgorod 603600 Russia

It is demonstrated that superconducting (SC) mechanism in doped Fe-based compounds is characteristic for itinerant electron systems with coexistence of both (e-e)- and (e-h)-pairing arising due to electron-phonon and Coulomb interactions, respectively. In such systems, with decreasing T first the dielectric (SDW) phase transition (and structural one) happens at $T = T^*$ (due to (e-h)-pairing) and only then, at $T = T_c$ ($T_c \leq T^*$), the SC transition starts (due to (e-e)-pairing), so that below T_c the system enters the coexistence (SC+SDW)-phase. (The thermodynamics of dielectric (SDW) phase transition here is the same as for superconductor). The corresponding dielectric (SDW) gap is highly anisotropic since it is only formed at symmetrical parts of the Fermi surface, and its magnitude Σ is large compared with that of SC gap Δ ($\Delta < \Sigma$). The SC transition in such systems happens at higher temperatures compared with conventional LTSC in BCS-system. Such high T_c is a natural consequence of (e-e)-pairing at the background of high density of states which singularity arises in the narrow energy range near dielectric-(SDW)-gap edges due to removing of electronic states from the energy region of dielectric (SDW) gap (already formed in the normal state). However, formation of the dielectric (SDW) gap at the Fermi surface leads to decreasing of energy region for (e-e)-pairing what, in its turn, leads, on the contrary, to decreasing of T_c. So, the maximum appears in the dependence of T_c (and hence Δ) as a function of doping. In contrast, the dielectric (SDW) gap Σ (and hence T^*) is a decreasing function of doping. Thus, these two doping dependencies are, in fact, forming a phase diagram of such system with interplay between of SC and magnetism. These conclusions follow from detailed analysis of available data on resistivity of doped Fe-based compounds (with taking into account the magnetic nature of parent compound ReOFeAs) as well as another experimental data on the basis of model with partial dielectrization of electron energy spectra. The picture obtained and manifestation of two order parameters (SC and SDW) in experiments, first of all, in threshold phenomena are discussed and some predictions are made. The comparison with the case of cuprates is performed.

I. INTRODUCTION

There was recently an essential progress in raise of critical temperature of superconducting transition T_c in newly discovered iron-based superconductors: for a short time period the superconducting critical temperature T_c has been raised from several Kelvins to 55 K [1, 2]. These superconductors are layered in crystal structure with alternate stacking $FeAs$ and LaO layers. $FeAs$-plane, with iron spins ordered antiferromagnetically, is considered as conducting one (cf. with CuO_2-plane in cuprates) while LaO layer serves as reservoir (for charge carriers) under doping. These compounds become to be superconducting with doping of parent (non-superconducting) compounds $ReOFeAs$ (where Re is a rare-earth element) which are a 'bad' (magnetic) metals with transition to commensurate static spin density wave (SDW) state below certain temperature ($\sim 150K$). This SDW transition in $ReOFeAs$ parent compound is near structural phase transition from tetragonal to orthorhombic phase what gives rise to anomaly in resistivity, optical, neutron and other experiments (for review, see, e.g. [3]) . However, attempts to detect the presence of SDW in superconducting Fe-based compounds in neutron, Mossbauer, transport experiments appear to be mostly unsuccessful, so that now it is wide belief that under doping of parent compounds the SDW order in ReOFeAs is displaced by SC one in doped compounds. In other words, the SDW and SC are considered as competing orders in these novel superconductors. In present paper, there are presented results of detailed analysis of resistivity data as well as another ones for novel iron-based superconductors on the basis of theory of itinerant electron systems with interplay between superconductivity and magnetism characterized by partial dielectrization of the electron energy spectra.

II. EVIDENCE FOR MAGNETIC (AF SDW) PHASE TRANSITION BEFORE SC ONE

As known, the resistivity of magnetic metals and alloys is usually decomposed in two main contributions: phonon $\rho_{ph}(T)$ and magnetic $\rho_m(T)$ ones (in neglecting of residual one)(see, e.g. [4])

$$\rho_{tot}(T) = \rho_{ph}(T) + \rho_m(T), \tag{1}$$

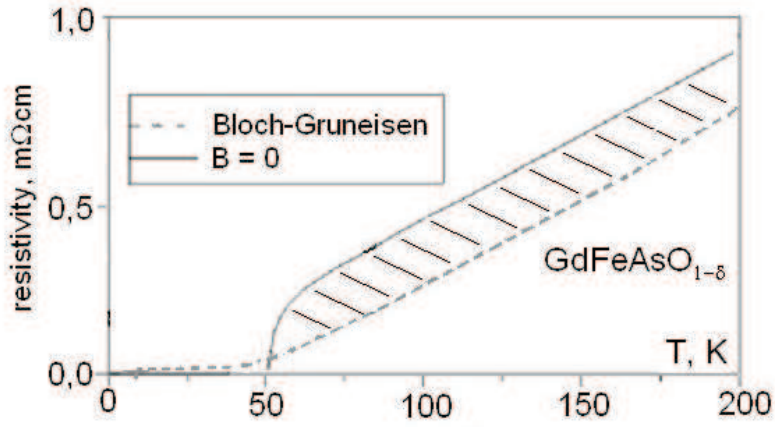

FIG. 1: Temperature dependence of resistivity for $GdAsFeO_{1-\delta}$ sample (data are close to [9]).

where phonon contribution is usually considered as corresponding to well known Bloch-Gruneisen expression (see, e.g. [5])

$$\rho_{ph}(T) = \rho_1(\frac{T}{\Theta_D})^5 \int\limits_0^{\Theta_D/T} \frac{x^5 dx}{(exp(x)-1)(1-exp(-x))} \quad , \tag{2}$$

and magnetic contribution $\rho_m(T)$ in paramagnetic region as (see, e.g. [4])

$$\rho_m(T) = \frac{(m/m_0)^2 N G^2 s(s+1)}{(\pi/3)^{1/3} e^2 h^3} n^{-2/3}. \tag{3}$$

The scaling parameter ρ_1 in (2) is determined by the slope of linear part of the $\rho(T)$ dependence, and parameters in (3) are usual (see, e.g. [4]): G is the coupling constant, s is the spin of fluctuating localized magnetic moments (LMM), N is the effective number of these LMM in unit volume, m and n are the effective mass and density of mobile charge carriers, respectively.

It is essential to note here that in (2), in addition to high-T linear region there exists an intermediate-T linear region ($0.22 \leq T/\Theta_D \leq 0.43$) characteristic for most metals (including magnetic ones) [5]. Namely, the latter, linear in T (not proportional (!) to T), region was considered in our earlier work [6] as corresponding to the normal state of the cuprates (see, also [8]).

The above decomposition procedure (see (1)) performed for $GdAsFeO_{1-\delta}$ sample (cf. with [9]) is presented in Fig.1. Note, that here $GdAsFeO_{1-\delta}$ is taken only as an example: such almost linear in T dependences are also observed in other superconducting samples with optimal doping in this family of Fe-based compounds (see, e.g. resistivity data for $SmO_{1-x}F_xFeAs$ in [10, 11]).

In Fig.1, solid line corresponds to experimental $\rho(T)$ dependence and dashed curve is a Bloch-Gruneisen (BG) one (see (2)). The data for BG-curve are fitted by us with $\Theta_D \approx 320K$ which value is close to that estimated from specific heat data for such compounds (see, e.g. [12]).

Then, the magnetic contribution to resistivity defined as $\rho_m(T) = \rho_{tot}(T) - \rho_{ph}(T)$ (see (1)) corresponds to the shadow region in Fig.1. Such suggestion is based on the fact that parent compounds $ReOFeAs$ are magnetic in nature, and with doping the AF spin fluctuations persist in the system providing an effective channel for scattering of mobile charge carriers in the normal state. (Note, such approach was before used by us for detailed analysis of the resistivity in cuprates since they are also of magnetic nature: parent compounds $YBa_2Cu_3O_6$ and La_2CuO_4 for SC cuprates as known are antiferromagnetic insulators.)

From Fig.1 it is seen that there are two distinct regions in this $\rho_m(T)$ dependence. Well in the normal state ($T > T_c$) the magnitude of ρ_m is high enough and nearly independent of temperature. Such behaviour corresponds to spin-disorder scattering of mobile charge carriers in paramagnetic region for

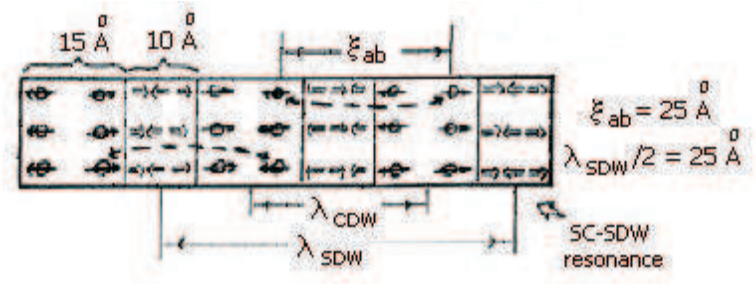

FIG. 2: The stripe structure in CuO_2-plane (scheme)(see, also [16]).

magnetic metals and alloys and, in conventional theory, resistivity due to such scattering can be expressed via (3) (cf. with [4]).

On the other hand, with decreasing temperature the magnitude of $\rho_m(T)$ decreases, and moreover, in the point of intersection of experimental $\rho(T)$ and BG curves, magnetic contribution to resistivity $\rho_m(T)$ disappears, so that at T below this intersection point the resistivity drop occurs only due to phonon contribution to resistivity. This disappearance of magnetic contribution at low temperatures is, in fact, the evidence for appearance of some magnetic ordering in the system, e.g. in the form of modulated magnetic structure (cf. with [13]) say, spin density wave (SDW) formed in the system near above T_c. So, two different magnetic phases exist in this system at low and high temperatures, respectively, and thus, decrease of $\rho_m(T)$ down to zero with decreasing temperature can be considered as indirect evidence for magnetic (AF SDW) phase transition in this system before the SC transition. In other words, resistivity drop due to SC transition in these compounds begins only from the point of intersection of experimental $\rho(T)$ and BG curves, and part of resistivity drop above this intersection point is attributed to magnetic (AF SDW) phase transition, i.e. the resistivity drop above the intersection point is essentially the normal state rather than SC one as it is usually considered.

Note that from the same analysis performed by us for cuprates before (see, e.g. [6, 8, 16]) it was suggested a stripe picture in the CuO_2-plane (see Fig.2). According to numerical simulation in the Hubbard model on a two-dimensional square lattice (for details, see [14]), the arrangement of each spin stripe is antiferromagnetic but two adjacent spin stripes are alternate to one other so that in the CuO_2-plane it is formed SDW with wavelength $\lambda_{SDW} = 50\mathring{A}$. The width of stripes in Fig.2 corresponds to that obtained in [15]. This SDW, because of its incommensurability, is accompanied by CDW with wavelength equal to one half of that for SDW: $\lambda_{CDW} = \lambda_{SDW}/2 = 25\mathring{A}$. Then, as it was obtained by us before [6], the in-plane coherence length $\xi_{ab} = 25\mathring{A}$, so that there is SC-SDW resonance in the system (cf. with Fig.1,2).

As its seen from Fig.2, for given stripe structure, electrons in charge stripes (arrows with circles) are oriented by spin stripes (double arrows) in a manner characteristic for the Cooper pairing in the s-wave BSC theory. (Note that same conclusion on the s-wave SC pairing symmetry follows from Fig.1, where SC transition starts only from point at phonon GB-curve as in conventional low-temperature superconductors (LTSC)).

III. THEORETICAL MODEL

The above picture is consistent with theory of interplay between magnetism and superconductivity in itinerant electron systems [17]. In such systems with interplay between SC and magnetism, with decreasing temparature, an itinerant SDW gap with magnitude Σ can appear at the Fermi surface only before the SC gap (Δ) (see Fig.3), i.e. in the normal state. This SDW gap is highly anisotropic since it is only formed at symmetric parts of the Fermi surface [17](see, inset in Fig.3). Its magnitude Σ being unusually large for the SC gap , well conforms to that for the SDW gap because of inequality $\Delta < \Sigma$ which is peculiar for the coexistence phase in that model (Fig.3). In such a case, the temperature T_c^{onset} (see, Fig.3) can be related to the appearance of the SC gap which begin develop at the Fermi surface only when the transition of the system to a magnetically-ordered (SDW) state is over.

Then, interrelations : $T_c^{onset} \leq T_{SDW}^{onset}$ and $T_c^{onset} = T_m^{order}$ can be a natural consequence of the equality of magnetic ordering energy ε_m^{order} and the condensation pair one ε_c^{pair} considered as characteristic for such itinerant electron system with an interplay between SC and magnetism. (Note here that namely such a picture was reported from elastic neutron scattering experiments (see, e.g. [18]) when in La -based

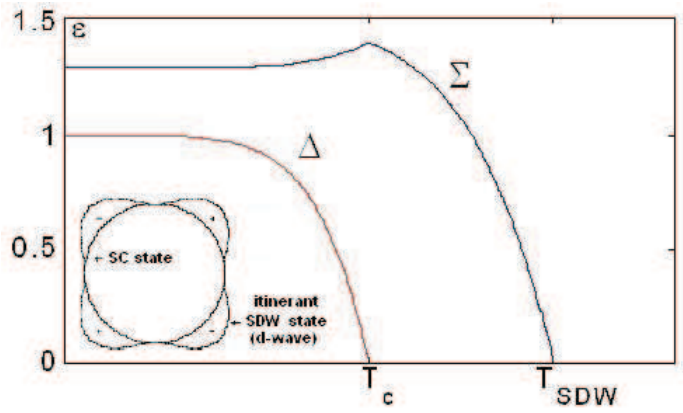

FIG. 3: Temperature dependence of SC and SDW order parameters (scheme). Inset: symmetry of SDW and SC states (for more details, see, e.g. [28]).

cuprate both the SC and static magnetic order appear at the same temperature).

Then, temperature and field behavior of such a system is essentially determined also by amplitude fluctuations of local spin density (FLSD)[19]: only slight effect of applied magnetic field (paramagnetic state) because of temperature-induced LMM regime of FLSD (spin disorder) above some temperature $T^*(H)$ in contrast to the enhancement of spin fluctuations by external magnetic field below $T^*(H)$ characteristic for AF systems (for references, see, e.g. [8]).

Such a theory is essentially based on the model with partial dielectrization of conduction electron energy spectrum (see, e.g. [20, 21]). So, for systems with both (e-h)- and (e-e)-pairing in which the SC and dielectric (DE) order parameters can coexist with one other, the Hamiltonian can be written as sum of three terms

$$H = H_i + H_{i,j} + H_{1,2}, \tag{4}$$

where i and j are the band indices ($i,\ j$ = 1,2) and H_i and $H_{i,j}$ describe intraband and interband interactions, respectively, while third term corresponds to the interband interactrion between electrons and static deformation $u(x)$ of the crystal lattice with coupling constant g_{12}^{eph}.

By using the method of temperature Green function [20] the matrix equation for the given system can be expressed as

$$A(\Delta_{i,j}, \Sigma, \zeta_i, \omega_n) \times B(G_{i,j}, F_{i,j}) = colon(1,0,0,0), \tag{5}$$

where $G_{i,j}$, $F_{i.j}$ are the Green functions, $\Delta_{i,j} = g_{i,j}F_{i,j}(x,x)$, $\Sigma = \tilde{g}_{21}G_{21}(x,x)$; $\zeta_i(p) = \mu \pm (p^2/2m - \varepsilon_F)$, μ is the shift of the Fermi level in each band due to doping; $\omega_n = \pi T(2n+1)$, n is the integer number; $g_{11},\ g_{22} < 0$ ((e-e)-attraction) are the constants of intraband interaction in the first term of (4) and responsible for electron-phonon (e-ph) and for Coulomb interaction (weakened due to the logarithmic factor $ln(\varepsilon_F/\omega_D)$); $g_{21}(< 0)$ is the analogous constant of interband interaction in the second term of (4); $\tilde{g}_{21} = g_{21} + 2(g_{21}^{eph})^2/\omega_D > 0$ is the constant responsible for (e-h)-pairing. The determinant for the system (5) can be written in the form [20]

$$Det = (\omega_n^2 + \omega_+^2)(\omega_n^2 + \omega_-^2), \tag{6}$$

where $\omega_\pm$ is the energy of elementary excitations in coexistent (SC + DE)-phase (see Fig.4)

$$\omega_\pm^2 = (\varepsilon \pm \tilde{\mu})^2 \qquad \varepsilon^2 = \zeta^2 + \tilde{\Sigma}^2. \tag{7}$$

The expression (7) in fact determines the dispersion relation for the system so that the electron energy spectrum in the (SC+DE)-phase of such systems is characterized by presence of two energy gaps (with different symmetry, in general case (cf. with [22])) at the Fermi surface: DE-gap with magnitude $\Sigma(T)$ due to (e-h)-pairing and SC-gap with magnitude $\Delta(T)$ due to (e-e)-pairing (see, Fig.4).

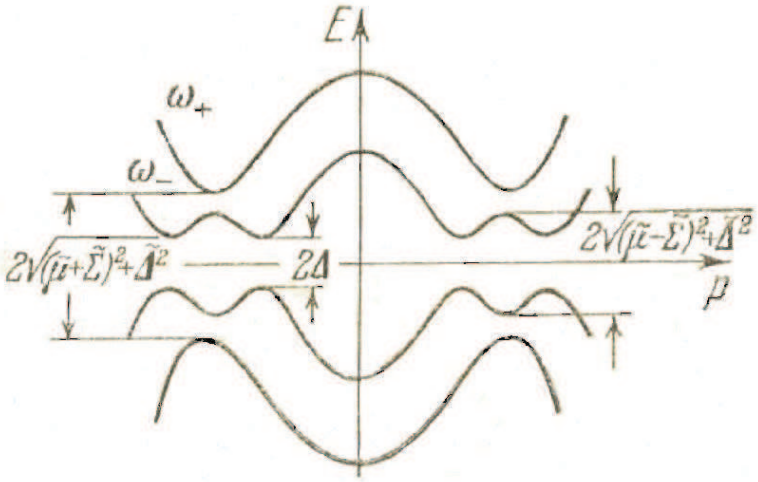

FIG. 4: Schematic electron energy spectra of coexistence phase of SC- and DE-pairings (see [21]).

From above theory it follows that in the systems under consideration with decreasing temperature firstly a structural (*dielectric*) transition occurs at $T = T^*$ ($T^* = T_{SDW}$ in our treatment) [20, 21, 24]. In result, a modulated lattice structure is formed in the system, and at $T = T^*(T_{SDW})$ the DE(SDW)-gap Σ begins to develop at symmetrical parts of the Fermi surface. With further decreasing T the magnitude of the DE(SDW)-gap Σ increases, then at $T = T_c$ the SC transition occurs and the SC gap Δ begins develop at the Fermi surface with decreasing temperature while the order parameter Σ becomes to decrease gradually approaching its zero-temperature value $\Sigma(0)$ (see, Fig.3).

The solution of (5) corresponding to the SC-gap in the (SC + DE)-phase (coexistence of (e-e)- and (e-h)-pairing) is given by

$$\tilde{\Delta} = 4\tilde{n}^2 exp(-\tilde{n}\beta^*/(\Sigma_0 - \tilde{n}))/\Sigma_0, \tag{8}$$

$$\beta^* = \beta_0/(1 - \beta_0\lambda_{21}\Sigma_0(\Sigma_0 - 2\tilde{n})/(\Sigma_0 - \tilde{n})^2), \tag{9}$$

where Σ_0 is the DE-gap in absence of doping; $\tilde{n} = \delta n/4N(0)$, δn is the difference of electron and hole densities, N_0 is the density of states near the Fermi level; $\beta_0 = ln(\Sigma_0/\Delta_0) > 0$, Δ_0 is the SC gap in absence of DE-pairing; $\lambda_{21} = g_{21}N(0)$ [20, 21].

On the other hand, for the DE-gap magnitude Σ it can be used the expression from [23]

$$\Sigma = 2\omega_0 exp(2\pi v_F/e^2 ln(\kappa_D^2/2p_0^2)), \tag{10}$$

which, in fact, describes the insulator with thermodynamics similar to that of superconductor.

IV. DISCUSSION

So, from above it follows that there should be two gaps (SC and SDW) with different nature in electron energy spectra of Fe-based superconductors at low temperature. Of course, fact of existence of two (SC and SDW) energy gaps (two (SC and SDW) order parameters) in the system should be taken into account at treatment of experiments, first of all, dealing with threshold phenomena like infrared absorption, nuclear spin relaxation, hypersonic absorption, tunneling experiments etc. in the (SC+DE(SDW in nature))-phase of such systems [21, 25]. It can be noted that at present, ARPES experiments should be also added to this list.

Since there are rather a few data for iron-based superconductors, and moreover, they are mainly obtained with polycrystalline samples then below there are also presented experimental data for cuprates, picture in which is believed to be essentially similar to that in iron-based compounds.

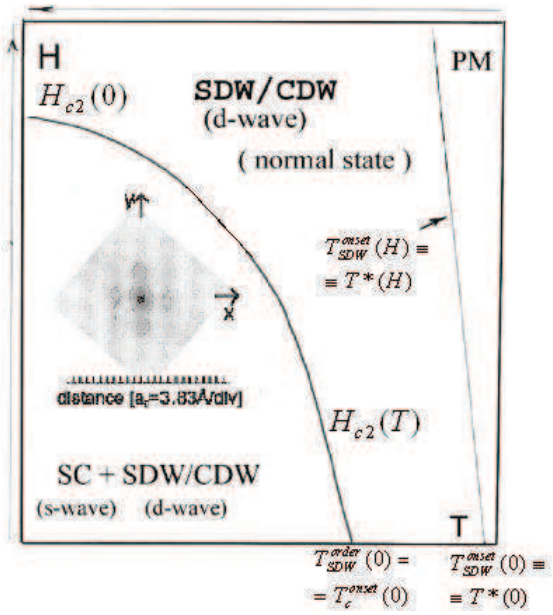

FIG. 5: Magnetic phase $H-T$ diagram for itinerant electron system with interplay between SC and magnetism. Inset: The in-plane checkerboard pattern in the vortex state of BSCCO single crystal from magnetic-field STM measurements (after [38]).

A. Manifestation of two energy gaps (two order parameters) in experiment

(AR) PES. Indeed, the evidence for two different energy gaps with different energy scale was recently observed in photoemission spectroscopy (PES) measurements in F-doped $LnOFeAs$ polycrystalline sample [26, 27]. However, since (AR) PES technique measures below T_c only the combined energy gap: $E=\sqrt{\Delta^2+\Sigma^2}$ rather than each of them separately, then it is necessary to take this fact into account under treament of measurements in superconducting state ((SC+SDW)-phase of Fe-based system), (cf. with that in cuprates, [28]).

Neutron scattering. From measurements with using of the neutron scattering technique up to now there was no observed evidences for SDW in doped Fe-based compounds in both normal and SC state, for both cases with and without of applied magnetic field [29].

However, in cuprates, in neutron diffraction experiments [30], it was obtained the evidence for antiferromagnetism of the vortex core in resistive state which in the underdoped single crystal of $La_{2-x}Sr_xCuO_4$ (x=0.1) is static in character (elastic neutron scattering) while in the optimally doped sample $La_{2-x}Sr_xCuO_4$ (x=0.163) enhancement of low frequency spin fluctuations in applied magnetic field was only observed (inelastic neutron scattering), and the vortex core antiferromagnetism was treated as field-induced for both samples. Moreover, the AF regions were also indicated in the space between vortices. Then, antiferromagnetic (SDW) ordering develops in LSCO just below the zero-field SC transition temperature $T_c(H=0)$ and increases with decreasing temperature and increasing field. However, this ordering in LSCO was considered in [30] only as field-induced though the zero-field magnetic response (when there are no SC vortices in the system) is also presented in the SC state, and the onset temperature of so defined AF (SDW) phase transition in zero- field case coincides, in fact, with that of zero-field SC transition: $T_m(H=0)=T_c(H=0)$ (cf. with Fig.5).

On the other hand, in work [31] where a zero-field elastic magnetic signal was observed, increasing with decreasing temperature and saturating at $T\to 0$, the behavior was noted as correspondent to the classical mean-field theory. Moreover, the same temperature behavior for the incommensurate magnetic signal was also observed in external magnetic field which fact was there treated as enhancement (rather than induction) of long-range magnetic order by magnetic field. Then, there was obtained a linear dependence of saturated at $T\to 0$ magnetic response on the magnetic field value characteristic for the vortex state. However, the onset temperature of the observed AF (SDW) phase transition was estimated as field-independent.

Note here, that nearly the same picture of modulated low-frequency spin fluctuations was obtained in YBCO single crystals from neutron scattering experiments in both the normal and superconducting

states (see, e.g., [32]). Moreover, a small magnetic signal was observed below $T \approx 200$ K which then increases below $T_c(H = 0)$.

Mossbauer spectroscopy. From ^{57}Fe Mossbauer spectroscopy measurements on La-family of Fe-based superconductors there was no observed also any evidence for SDW order in the whole temperature range of interest (see, e.g. [3]). However, in [33] on the basis of the same measurements as well as magnetic ones in $SmFeAsO_{0.85}$ superconductor it was obtained an evidence for coexistence of SC and magnetism in the FeAs-layer (cf. with Fig.2 in present paper). Then, from the Mossbauer spectra in the normal state it was obtained a well-defined quadrupole doublet while in the SC state a magnetic sextet was developed. The possibility of these observations could be provided due to the coupling between the Sm and Fe moments in the system which is absent in LaOFeFAs superconductors.

μSR. From muon spin relaxation measurements (which a time window is usually in the range between 10^{-6} and 10^{-9} s [34]) in $LaO_{0.97}F_{0.03}FeAs$ it was obtained an evidence for possible incommensurate or stripe magnetism (cf. with Fig.2 in present paper): Bessel-function line shape of time spectra of zero-field μSR characteristic for such magnetism was observed for doped compounds [35].

Tunneling. In the point-contact spectroscopy measurements there was obtained a peak-dip-hump structure in tunneling spectra [36] which is reminiscent to the case of cuprates where such structure was obtained e.g., in STM measurements [37]. There, from such measurements with single crystal Bi-2212 it was obtained the peak-dip-hump structure considered as evidence for two energy gaps in the electron energy spectra and a pseudogap appears to be in the role of the DE-gap (note that according to our treatment, the PG is of SDW/CDW nature) (for more details, see [28]). Moreover, while in [37] the SC-gap with increasing T disappears at $T = Tc$ ($\Delta = 0$), the DE-gap (PG(SDW)) magnitude is not zero and $\Sigma(T)$ vanishes only well in the normal state.

On the other hand, from magnetic-field STM experiments with $Bi_2Sr_2CaCu_2O_{8+\delta}$ single crystal [38], on the basis of detailed comparison of STM pattern of the sample surface in high magnetic field with that in zero-field case, a checkerboard pattern was visualized inside and outside the vortex core (see insert in Fig. 5). There, it was concluded also about the field-induced nature of the periodicity in the measured local density of electron states (LDOS). Though the STM method is insensitive to the magnetism, it was proposed by them that the incommensurability of the in-plane LDOS modulation observed below $T_c(H = 0)$ corresponds to the SDW/CDW picture (stripe structure with alternating spin and charge stripes (for review, see [15])) with the wavelength $\lambda_{CDW} = \lambda_{SDW}/2$ characteristic for general theory of SDW systems (see, e.g., [39]) which interrelation between spin and charge stripes was actually obtained there.

Note here, that in addition, in another low temperature magnetic-field STM measurements in cuprates the evidence for the pseudogap with d-wave symmetry in the vortex core (the same as in the normal state) was observed so that SDW nature of the pseudogap was proposed (for references, see [40]).

NMR. NMR experiments performed with novel Fe-based superconductors can be also considered as consistent with two energy gap (SC and SDW) picture in above theoretical model (see, Sec.3). So, in ^{75}As NMR measurements performed on $LaO_{0.9}F_{0.1}FeAs$ superconductor [41] it was obtained the evidence for pseudo-spin gap in the normal state which gives rise to a suppression of magnetic shift K_s arising via a hyperfine coupling to electron spins and spin lattice relaxation rate T_1^{-1} for temperatures below 300 K, moreover, decreasing of magnetic shift in the SC state is considered in [41] as suggestive for spin-singlet pairing. The temperature dependent Knight shift in F-doped $LaOFeAs$ was also concluded to be similar to pseudogap (SDW-gap in present treatment) behaviour in cuprates.

In this connection, it should be noted recently presented results of spatially resolved high-field NMR studies of optimally doped YBCO (for references, see [28]) where indication was also obtained for the presence of correlated antiferromagnetic fluctuations in the vortex core. The method used the similarity of a spatial distribution of the internal magnetic field in the vortex lattice and the NMR spectrum for any nucleus with small intrinsic broadening (e.g., for ^{17}O in YBCO).

It should also be noted that above proposal was supported by magnetic-field NMR measurements in cuprates, in which the absence of any shift of the pseudogap (SDW, in our treatment) onset temperature T^* up to high enough magnetic field was observed while the SC transition temperature $T_c(H)$ was essentially shifted downwards to zero [43]. This fact was considered there as evidence for the relatively large energy scale for the pseudogap mechanism which scale is rather characteristic for the density waves (e.g., SDW/CDW state).

B. Static vs. quasi-static additional (magnetic) order in superconducting Fe-based compounds

Note, that though in cuprates such magnetic phase transition has no been directly seen before but its possibility was discussed anywhere and some evidences was obtained (for details, see [40]). Moreover, as it was noted in a number of works, it's direct observation by the normal neutron scattering can appear to be problematic because of specificity of the low-temperature quasi-static magnetic ordering. The same situation can be realized in Fe-based compounds as well.

So, from above it can be concluded that in these compounds below $T_c(H = 0)$ a periodic spatial modulation of magnetization considered as static (elastic peaks) or as fluctuating (inelastic signal) one is observed. Such a behavior can be regarded as evidence for the AF SDW ordering which is dynamical in nature, in general case. In this sense, the low energy (i.e., dynamic) incommensurate spin excitations in the system can correspond to the dynamic formation of stripes and moreover, in cuprates, dynamic nature of stripes is even stronger in LSCO ($x \approx 0.125$) though stripes are frequently (and erroneously) considered as static below $T = 20K$ based on elastic neutron scattering data. In addition, it was demonstrated in [44] that static stripes are not really static even at 350 mK. Thus, even static ordering (stripe structure) cannot be regarded as really static but only depending on the timescale of the local probe (cf. with [40]). In other words, the question 'is the observed (SDW) order static or fluctuating one' is determined by the relation between characteristic frequency of spin fluctuations and timescale of concrete local probe. So, according to [44], the critical temperature to observe the spin ordering T_{spin} is lower for experimental probes with slower frequency scales, i.e., $T_{spin} \sim 50K$ for elastic neutron scattering ($\sim 10^{11}Hz$), $T_{spin} = 30K$ for μSR ($\sim 10^{7}Hz$) and $T_{spin} = \sim 10-30K$ for NQR ($\sim 10^{6}Hz$). In addition, the spin fluctuation frequency appears to be dependent on temperature so that in some temperature regions in cuprates it was observed a slowing down effect which leads to wipeout of the NMR signal and, in result, the SDW ordering (stripe structure) appears to be undetectable with the given local probe. In this sense, such a problem is in fact absent for the conduction electron scattering which provides the electrical resistivity of metals. Indeed, in resistivity measurements, due to short mobile charge carrier relaxation time, a magnetic structure is sampled on much shorter time scale as compared with many other techniques such as neutron scattering, Mossbauer effect (cf. with neutron and Mossbauer spectroscopy results in Fe-based superconductors in Sec.4A, see above), etc. (see, also [40] and references therein).

Then, note also that during the study of cuprates it was introduced a concept of so-called 'hidden' order in the cuprates (for references, see, e.g. [40]). Such an order is attributed to d -density wave (DDW) order. However, in their statement the type of this DDW order is not concrete but it is only considered as competing (not vital) order for SC one, moreover it is considered as corresponding to the superconductivity with $d_{x^2-y^2}$ -wave pairing symmetry. As follows from above this concept can be described in terms of the (spin) density wave (S) (DW) (and (charge) density wave (C) (DW) with $\lambda_{CDW} = \lambda_{SDW}/2$) state with a $d_{x^2-y^2}$ -wave symmetry (see above). The effects of these density waves (DW) are well known and the 'hiddenness' of these (DW) in the cuprates can be of natural consequence of the dynamical nature of these (S) and (C) (DW) so that only fast and local probe (including resistivity measurements) permits to detect these (DW) concretely.

C. Phase diagram of Fe-based superconductors

.

From above theory it follows that doping dependence of magnitude of SC gap (Δ) and DE (SDW) one (Σ) in such a system should be quite different. The superconducting gap (8) (as well as critical temperature T_c) has a maximum as a function of the carrier density. This maximum appears due to the competition between increase in the density of states at the edges of the dielectric gap (singularity) as result of (e-h)-pairing and decrease of energy interval with electrons near the Fermi level as result of the DE (SDW) gap formation [20, 21]. Such conclusion is also consistent with expression obtained in [22]

$$T_c = 1.14(\omega^2)^{1/2}(\mu/\Sigma)exp(-(\mu/\Sigma)/\lambda N(0)), \tag{11}$$

where λ is the effective constant of (e-ph)-interaction, ω is the average value of phonon frequency. Moreover, maximum value of temperature of superconducting transition can be essentially higher as compared with T_{c0} in absence of dielectric (SDW) (e-h)-pairing [20, 21]

$$(T_c/T_{c0})_{max} = 4exp\beta_0/e\beta_0, \tag{12}$$

As for DE(SDW) gap Σ then it (and SDW onset temperature T^*) is decreasing function of doping (see (10)). So, as a result, these two dependencies in fact determine the phase diagram of the Fe-based system.

In this connection, there can be interesting the recent results of electronic Raman scattering experiments [45] in which indication to two energy scales in the SC state of cuprates are presented. First, characteristic energy (corresponding to magnitude of the SC-gap Δ, and thus to that of T_c) measured in a nodal region of momentum space has a maximum as a function of doping (cf. with (8) and (11)). Such $\Delta(p)$-dependence with maximum is characteristic for the SC order parameter with s-wave symmetry in the model of [20, 21]. In contrast, second characteristic energy (corresponding to magnitude of the DE(SDW)-gap Σ and thus T^*) measured in antinodal region appears to be decreasing function of doping, in agreement with theory [23]. Such a picture is consistent also with our model for symmetry of the two order parameters in cuprates: s-wave for SC one and d-wave for DE(SDW) one (see insert in Fig. 3)(cf. with [16, 42]).

D. Magnetic phase $H-T$ diagram; upper critical field $H_{c2}(0)$

The above decomposition procedure (see (1)) permits to obtain the magnetic phase $H-T$ diagram in the whole temperature range of interest (see Fig.5) from resistivity data in a magnetic field by a correct way. In contrast to the problem with so-called 'upward curvature' of $H_{c2}(T)$ curve near $T_c(H=0)$ discussed in literature, e.g. in 'mid-point' or 'zero-resistance' methods, the decomposition procedure (see (1)) provides correct data for this diagram from points of intersection of experimental $\rho(T)$ dependencies in applied magnetic field with BG curve, and so formed $H_{c2}(T)$ dependence appears to be linear in T near $T_c(H=0)$ as in BCS and GL theories (see, e.g. [6, 8]). The data to form a $T^*(H)$ dependence for SDW can be taken from characteristic points at experimental $\rho(T)$ dependencies in a magnetic field corresponding to beginning of deviation from linearity in T with decreasing temperature (for details see, e.g [6, 7, 8]). (Note that according to above (Sec. 4B), the magnetic phase $H-T$ diagram for compounds under study (see Fig.5) should be considered as dynamic in nature).

In this magnetic phase $H-T$ diagram the results discussed above can be accounted for by a natural way. The point in the (SC+SDW)-state (antiferromagnetic (SDW) order in the SC state) at the (H,T) plane can be reached by two different ways. First, it can be reached under cooling in a constant external magnetic field. But, if one will reach this point by increasing the external magnetic field at given temperature then antiferromagnetic (SDW) order will be looked as 'field-induced' though it has only emerged in the core of vortices since, and as follows from above, the SDW/CDW state can be regarded as underlying order for the SC one in the cuprates and Fe-based SC compounds.

E. On ferromagnetism and superconductivity in novel superconductors

It is sometimes considered as surprizing that strong magnetic element Fe normally giving rise to magnetic moments, and in many cases forming a long range ferromagnetic order, and being thus detrimental to the superconductivity with singlet pairing play an important role in superconductivity. However, the problem of coexistence of ferromagnetism and superconductivity was else discussed by Ginzburg in his earlier work about ferromagnetic superconductors [46]. There it was demonstrated that ferromagnetism and superconductivity can coexist with one other if the internal ferromagnetic molecular field is weaker compared with zero-temperature thermodynamic critical field $H_{c2}(0)$ of superconductivity. In other words, under conventional conditions, ferromagnetic sample can enter the SC state only in exclusive cases, when its sponaneous magnetization M_0 (at $T=0$) is very low ($B_0=4\pi M_0 \leq 1T$), while upper critical field should be high enough ($\geq 1T$). Since the upper critical field $H_{c2}(0)$ for conventional LTSC is between 0,26 T (for Nb) and 0,0026 T (for Gd) then it is not the case for LTSC but it appears to be the case for novel Fe-based superconductors where H_{c2} was estimated as near above 60 T [47] (for comparison, the value of B_0 for sample of pure Fe is only near 2,2 T). Note the results of [12] in which the temperature of maximum in difference of electronic specific heat coefficients $\gamma(H=0)-\gamma(H=9T)$ is consistent with that of intersection point of experimental $\rho(T,H=9T)$ curve with BG one (cf. with Fig.1), i.e. with T_c^{onset} at $H=9T$, from what it follows that the upper critical field $H_{c2}(0)$ estimated from the data in [12] according to BCS and GL theories, appears to be near 20T. It is essential, however, these values overestimate the real value of upper critical field for $\vec{H}\|\vec{c}$ case due to polycrystalline structure of samples, since $\vec{c}$-axes are randomly oriented into the sample. But the latter value of $H_{c2}(0)$ will be, of course, higher then 2,2 T (see, above).

F. The nature of strong suppression of T_c by non-magnetic impurities in (SC+SDW) state

Another issue which is described by the above theory (see Sec.3) in a natural way is the suppression of T_c by nonmagnetic impurities which effect is not the case for LTSC. So, in the (SC + DE)-coexistence phase the values of Σ and T^* being influenced by scattering with nonmagnetic impurity, will be also, in their turn, influent the values Δ and T_c because of strong correlation of later ones with Σ and T^* ($= T_{SDW}$, in our treatment) (see, e.g. [21]). This effect of depairing of (e-h)-pairs by nonmagnetic impurities (in analogy with depairing of (e-e)-pairs by magnetic impurities in LTSC) determines both strong suppression of T_c and decrease of the DE-gap (PG, SDW/CDW-gap [6, 42]) with increasing the impurity concentration which effect was observed in cuprate systems,[48]. In contrast, in the case of magnetic impurity, there should take place an increase of the magnitude of DE-gap (PG, SDW/CDW-gap [6, 42]) (also observed in [48]) due to polarization of impurity by the SDW, leading to an exchange enhancement of the SDW, the effect well known for AFM systems with itinerant electrons (for details, see [28]).

V. CONCLUSION

From preliminary analysis performed above it can be concluded the following. The doped Fe-based compounds are related to systems with both (e-e)- and (e-h)-pairings due to electron-phonon and Coulomb interactions, respectively. In such systems, with decreasing temperature, firstly it occurs a dielectric (DE) phase transition (and structural one) at $T = T^*$ (due to (e-h)-pairing) and only then SC one (due to (e-e)-pairing) at $T = T_c$ so that below T_c the system enters the coexistence (SC +DE) phase. The thermodynamics of dielectric transition is the same as for superconductor. During this process, the dielectric gap is formed only at the part (s) of the Fermi surface. High T_c of the SC transition in such system is reached since (e-e)-pairing occurs at the background of high density of states (singularity) arising in energy region near dielectric-gap edges due to removing of electronic states from the energy region of the dielectric gap (already formed in the normal state). (It is well known that in BCS-theory the SC transition temperature T_c is highly sensitive to the density of states value). Such conditions arise when parameters of the system, changing with e.g. doping, appear favourable for Fermi level to be located in the energy region with high density of states (singularity) at the edges of the dielectric gap. However, because of formation of the DE-gap at the Fermi surface the energy region for (e-e)-pairing is decreased what leads to decreasing of T_c. So, it should appear a maximum in dependence of T_c (and hence of Δ) as a function of doping (optimal doping). In contrast, the DE-gap (and hence T^*) is a decreasing function of doping. Thus, these two doping dependences can be considered as forming a phase diagram of the system.

Such a theory, being applied to itinerant electron system with interplay between superconductivity and magnetism, leads to formation of anisotropic SDW-gap (as dielectric gap) at symmetrical parts of the Fermi surface well before SC transition. This SDW in doped Fe-based compounds appears to be incommensurate with lattice (in contrast to commensurate one in parent compounds $ReOFeAs$) and it is accompanied by CDW with wavelength equal to one half of that for SDW so that in FeAs-plane it should be formed a stripe-like structure with alternating spin and charge stripes. The SDW order parameter is dynamical in nature, and its detection depends on timescale of technique used. The magnetic field being applied provides the periodicity (SDW/CDW structure) inside the vortex core region at T below $H_{c2}(T)$ curve at the magnetic phase $H - T$ diagram, while above $T^*(H)$ curve at this diagram the SDW state is absent at all.

Of course, the above analysis was performed on the basis of available data for polycrystalline samples of doped Fe-based compounds and more correct conclusions can be obtained only when measurements on single-crystal samples of Fe-based superconductors will appear, however, it seems that the general picture remains to be the same.
